

Ask Question

# A list of cost functions used in neural networks, alongside applications

Asked 4 years, 11 months ago Active 1 year, 7 months ago Viewed 154k times

What are common cost functions used in evaluating the performance of neural networks?

### 148 Details

(feel free to skip the rest of this question, my intent here is simply to provide clarification on notation that answers may use to help them be more understandable to the general reader)

**4**3

I think it would be useful to have a list of common cost functions, alongside a few ways that they have been used in practice. So if others are interested in this I think a community wiki is probably the best approach, or we can take it down if it's off topic.

#### **Notation**

So to start, I'd like to define a notation that we all use when describing these, so the answers fit well with each other.

This notation is from Neilsen's book.

A Feedforward Neural Network is a many layers of neurons connected together. Then it takes in an input, that input "trickles" through the network and then the neural network returns an output vector.

More formally, call  $a_i^i$  the activation (aka output) of the  $j^{th}$  neuron in the  $i^{th}$  layer, where  $a_i^1$  is the  $j^{th}$ 

$$a_j^i = \sigma(\sum_k (w_{jk}^i \cdot a_k^{i-1}) + b_j^i)$$

where

 $\sigma$  is the activation function,

 $w_{jk}^{i}$  is the weight from the  $k^{th}$  neuron in the  $(i-1)^{th}$  layer to the  $j^{th}$  neuron in the  $i^{th}$  layer,

 $b_{j}^{i}$  is the bias of the  $j^{th}$  neuron in the  $i^{th}$  layer, and

 $a_i^i$  represents the activation value of the  $j^{th}$  neuron in the  $i^th$  layer.

Sometimes we write  $z_j^i$  to represent  $\sum\limits_k (w_{jk}^i \cdot a_k^{i-1}) + b_j^i$ , in other words, the activation value of a neuron before applying the activation function.

For more concise notation we can write

$$a^i = \sigma(w^i \times a^{i-1} + b^i)$$

To use this formula to compute the output of a feedforward network for some input  $I \in \mathbb{R}^n$ , set  $a^1 = I$ , then compute  $a^2$ ,  $a^3$ , ..., $a^m$ , where m is the number of layers.

#### Introduction

A cost function is a measure of "how good" a neural network did with respect to it's given training sample

whole.

Specifically, a cost function is of the form

$$C(W, B, S^r, E^r)$$

where W is our neural network's weights, B is our neural network's biases,  $S^r$  is the input of a single training sample, and  $E^r$  is the desired output of that training sample. Note this function can also potentially be dependent on  $y_j^i$  and  $z_j^i$  for any neuron j in layer i, because those values are dependent on W, B, and  $S^r$ .

In backpropagation, the cost function is used to compute the error of our output layer,  $\delta^L$ , via

$$\delta_j^L = \frac{\partial C}{\partial a_j^L} \sigma'(z_j^i)$$

Which can also be written as a vector via

$$\delta^{L} = \nabla_{a} C \odot \sigma'(z^{i})$$

We will provide the gradient of the cost functions in terms of the second equation, but if one wants to prove these results themselves, using the first equation is recommended because it's easier to work with.

## **Cost function requirements**

To be used in backpropagation, a cost function must satisfy two properties:

1: The cost function C must be able to be written as an average

$$C = \frac{1}{n} \sum_{x} C_{x}$$

over cost functions  $C_x$  for individual training examples, x.

This is so it allows us to compute the gradient (with respect to weights and biases) for a single training example, and run Gradient Descent.

2: The cost function C must not be dependent on any activation values of a neural network besides the output values  $a^L$ .

Technically a cost function can be dependent on any  $a_j^i$  or  $z_j^i$ . We just make this restriction so we can backpropagte, because the equation for finding the gradient of the last layer is the only one that is dependent on the cost function (the rest are dependent on the next layer). If the cost function is dependent on other activation layers besides the output one, backpropagation will be invalid because the idea of "trickling backwards" no longer works.

Also, activation functions are required to have an output  $0 \le a_j^L \le 1$  for all j. Thus these cost functions need to only be defined within that range (for example,  $\sqrt{a_j^L}$  is valid since we are guaranteed  $a_j^L \ge 0$ ).

community wiki Phylliida

This is a Q&A site, and the format of this post doesn't really fit that. You should probably put the majority of the content in an answer, and leave just the question (e.g. What is a list of cost functions used in NNs?). – Roger Fan May 31 '15 at 19:47

Okay, is that better? I think the definitions are important otherwise the answers become vague for those that aren't familiar with the terminology the writer uses. – Phylliida May 31 '15 at 19:49

But what if a different answer uses different notation or terminology? - Roger Fan May 31 '15 at 19:52

- The idea is that everyone uses the same terminology here, and that if it's different we convert it to this, so the answers "fit" with each other. But I suppose I could remove that piece if you don't think it's helpful. Phylliida May 31 '15 at 19:54
- 1 I just think the detail the question goes into isn't really necessary or relevant. It seems a bit excessive and limiting, but that's just me. Roger Fan May 31 '15 at 19:56

#### 2 Answers

Here are those I understand so far. Most of these work best when given values between 0 and 1.

### 92 Quadratic cost

Also known as mean squared error, maximum likelihood, and sum squared error, this is defined as:

$$C_{MST}(W, B, S^r, E^r) = 0.5 \sum_{j} (a_j^L - E_j^r)^2$$

The gradient of this cost function with respect to the output of a neural network and some sample r is:

$$\nabla_a C_{MST} = (a^L - E^r)$$

## **Cross-entropy cost**

Also known as Bernoulli negative log-likelihood and Binary Cross-Entropy

$$C_{CE}(W, B, S^r, E^r) = -\sum_{j} [E_j^r \ln a_j^L + (1 - E_j^r) \ln (1 - a_j^L)]$$

The gradient of this cost function with respect to the output of a neural network and some sample r is:

$$\nabla_a C_{CE} = \frac{(a^L - E^r)}{(1 - a^L)(a^L)}$$

# **Exponentional cost**

This requires choosing some parameter  $\tau$  that you think will give you the behavior you want. Typically you'll just need to play with this until things work good.

where  $\exp(x)$  is simply shorthand for  $e^x$ .

The gradient of this cost function with respect to the output of a neural network and some sample r is:

$$\nabla_a C = \frac{2}{\tau} (a^L - E^r) C_{EXP}(W, B, S^r, E^r)$$

I could rewrite out  $C_{\it EXP}$ , but that seems redundant. Point is the gradient computes a vector and then multiplies it by  $C_{\it EXP}$ .

### Hellinger distance

$$C_{HD}(W, B, S^r, E^r) = \frac{1}{\sqrt{2}} \sum_{j} (\sqrt{a_j^L} - \sqrt{E_j^r})^2$$

You can find more about this <u>here</u>. This needs to have positive values, and ideally values between 0 and 1. The same is true for the following divergences.

The gradient of this cost function with respect to the output of a neural network and some sample r is:

$$\nabla_a C = \frac{\sqrt{a^L} - \sqrt{E^r}}{\sqrt{2}\sqrt{a^L}}$$

## Kullback-Leibler divergence

Also known as *Information Divergence*, *Information Gain*, *Relative entropy*, *KLIC*, or *KL Divergence* (See here).

Kullback-Leibler divergence is typically denoted

$$D_{\mathrm{KL}}(P \parallel Q) = \sum_{i} P(i) \ln \frac{P(i)}{Q(i)}$$

,

where  $D_{\mathrm{KL}}(P \parallel Q)$  is a measure of the information lost when Q is used to approximate P. Thus we want to set  $P = E^i$  and  $Q = a^L$ , because we want to measure how much information is lost when we use  $a^i_j$  to approximate  $E^i_j$ . This gives us

$$C_{KL}(W, B, S^r, E^r) = \sum_{j} E_j^r \log \frac{E_j^r}{a_j^L}$$

The other divergences here use this same idea of setting  $P = E^i$  and  $Q = a^L$ .

The gradient of this cost function with respect to the output of a neural network and some sample r is:

$$\nabla_a C = -\frac{E^r}{I}$$

From here.

$$C_{GKL}(W, B, S^r, E^r) = \sum_{j} E_j^r \log \frac{E_j^r}{a_i^L} - \sum_{j} (E_j^r) + \sum_{j} (a_j^L)$$

The gradient of this cost function with respect to the output of a neural network and some sample r is:

$$\nabla_a C = \frac{a^L - E^r}{a^L}$$

#### Itakura-Saito distance

Also from here.

$$C_{GKL}(W, B, S^r, E^r) = \sum_{j} \left( \frac{E_j^r}{a_j^L} - \log \frac{E_j^r}{a_j^L} - 1 \right)$$

The gradient of this cost function with respect to the output of a neural network and some sample r is:

$$\nabla_a C = \frac{a^L - E^r}{\left(a^L\right)^2}$$

Where  $\left(\left(a^L\right)^2\right)_j = a_j^L \cdot a_j^L$ . In other words,  $\left(a^L\right)^2$  is simply equal to squaring each element of  $a^L$ .

Thanks for sharing, you can also consider these: <u>github.com/torch/nn/blob/master/doc/criterion.md</u> – Yannis Assael May 31 '15 at 19:52

- you have a small mistake in the denominator of the cross-entropy derivative, it should be a\* (1-a) not a\* (1+a) Amro May 16 '16 at 17:51
- 1 It would also be cool to show the pinball loss function to minimize error quantiles rather than average error. Very used in decision support systems. Ricardo Cruz Nov 10 '16 at 13:56

where can I see graphs for these? - coiso Aug 24 '18 at 15:46

1 With regards to the Quadratic Cost Function, you should note that "mean squared error" ≠ "maximum likelihood" ≠ "sum squared error". Authors may use the name (incorrectly) interchangeably, but they are *not* the same thing. – Jon Jan 2 '19 at 19:26

show 2 more comments

Don't have the reputation to comment, but there are sign errors in those last 3 gradients.

Log in

$$= \sum_{j} E_{j} \log(E_{j}) - E_{j} \log(a_{j})$$

$$dC = -\sum_{j} E_{j} d\log(a_{j})$$
$$= -\sum_{j} (E_{j}/a_{j}) da_{j}$$

$$\nabla_a C = \frac{-E}{a}$$

This same sign error appears in the Generalized KL divergence.

In the Itakura-Saito distance,

$$C = \sum_{j} (E_{j}/a_{j}) - \log(E_{j}/a_{j}) - 1$$

$$= \sum_{j} (E_{j}/a_{j}) - \log(E_{j}) + \log(a_{j}) - 1$$

$$dC = \sum_{j} (-E_{j}/a_{j}^{2}) da_{j} + d\log(a_{j})$$

$$= \sum_{j} (1/a_{j}) da_{j} - (E_{j}/a_{j}^{2}) da_{j}$$

$$= \sum_{j} (a_{j} - E_{j})/a_{j}^{2} da_{j}$$

$$\nabla_{a}C = \frac{a - E}{(a)^{2}}$$
